Petiole Sap Analysis - A Quick Tissue Test for Nitrogen in Potatoes

Mal Westcott

Montana State University

Potato growers have reliably used petiole nitrate (NO₃) testing for years as a means of monitoring the nitrogen (N) status of their crop during the growing season. This is a particularly effective technique in potato production, since the petiole is a very sensitive indicator of current soil N supply, and management practices such as supplemental N application through irrigation systems (fertilization) allow for corrective measures when deficiencies or excesses are detected.

The chief limitation to petiole testing is the amount of time required to dry samples, send them to a commercial lab for analysis, and then receive the results. This takes at least several days, and more typically a week or more. The problem is that, while petiole N03 analysis gives the grower information about current soil N availability, the information may be received after-the-fact. The development of a quick method for analysis in the field or on-site would greatly improve the application of tissue testing. The grower or consultant could combine immediate information from analysis with observations in the field to make decisions about adjustments to fertilization programs.

Petiole sap analysis for N03 concentration is proposed as a quick test method to provide immediate information about crop N status. Instruments are commercially available that can be used to directly measure N03 concentration in relatively small quantities of liquid and that do not require a laboratory setting for accurate calibration and use. One such instrument is the Cardy (N03 meter (no endorsement of this product is intended, nor is criticism implied of similar products not mentioned) which is pocket-size, currently costs about $300, and is simple to use. A sample size normally collected for petiole testing with conventional methods will yield more than sufficient sap to obtain a reading with this type of meter. Sap extraction and analysis can be completed in the field.

The development of a new plant diagnostic technique requires the identification of critical nutrient levels (below which a yield reduction occurs) in the specific plant tissue and with the specific analytical method being proposed. This is usually done by establishing the relationship between crop yield and measured tissue nutrient levels. In the case of conventional petiole testing, critical nutrient levels in dry petiole tissue have been well established in virtually all potato growing areas. It would be a time-consuming, costly process to perform the same amount of work in calibrating a new technique such as petiole sap analysis. However, development of a sap quicktest would be fairly simple if there is a good relationship between petiole sap NO₃ concentration and petiole dry matter NO₃ concentration. Such a relationship would allow the simple conversion of established critical values for petiole dry matter NO to critical values for petiole sap NO₃.

The research reported here establishes this relationship and provides critical values for petiole sap NO₃ analysis. Russet Burbank potatoes were grown in 1990 and 1991 on a Creston silty loam at the Northwestern Agricultural Research Center in Kalispell in a replicated field trial with irrigation amounts and N fertilizer timings as treatments, thereby establishing a wide range in crop water and N status for comparison of the two analytical procedures. Petiole samples were collected from four specified irrigation levels in each of the N treatment plots on a weekly or biweekly basis beginning in early July through the remainder of the growing season. A total of 80 samples, 30 to 40 petioles per sample, was collected on each of the five or six sampling dates each year.
The sap from 15 to 20 petioles in each sample was extracted and analyze for NO₃ concentration using the Cardy NO₃ meter. The remaining petioles were dried and saved for later analysis for dry matter NO₃ concentration according to the conventional protocol for petiole testing. Results were compared between the two methods.

There was a consistent relationship between sap NO₃-N concentration and dry matter NO₃-N concentration in potatoes across both years of testing (Figure 1). The only problem encountered was the upper detection limit of the Cady meter which is 10,000 ppm NO₃ or 2,258 ppm NO₃-N. Sap NO₃ at this level corresponds to dry matter levels of about 20,000 ppm NO₃-N. The result was a loss of accuracy in the higher readings early in the growing season. This problem may be overcome by calibrating the meter on a NO₃-N basis instead of a NO₃ basis, as was employed in this research.

With petiole dry matter NO₃-N levels ranging up to 20,000 ppm, as typically found during the tuber bulking period, the relationship between sap NO₃-N and dry matter NO₃-N is:

\[
\text{Sap NO₃-N} = (0.085 \times \text{Dry Matter NO₃-N}) + 322, \text{ using units of ppm.}
\]

This equation can be used to convert existing petiole NO₃ criteria to use in sap analysis. Conversely, it may be desired to convert sap readings to dry matter readings for comparison. In that case:

\[
\text{Dry Matter NO₃-N} = (11.8 \times \text{Sap NO₃-N}) - 3,800, \text{ again using ppm.}
\]

A conversion chart (Table 1) is included to make this process more convenient, with established criteria noted. The potato petiole sap quicktest method for NO₃ concentration using a portable NO₃ meter is ready for field application using the conversion equations or table included here. The meter is fairly simple to use, but several words of advice in using this new method are warranted:

1. All units reported here are on a ppm NO₃-N basis. If the standards used in calibration are expressed on a NO₃ basis, then meter readings can be converted to a NO₃-N basis by multiplying by 0.226.
2. If calibrated on a NO₃ basis, the upper detection limit of the meter will limit its use to the period after tuber initiation.
3. The sample to be analyzed should be representative of the field being tested and the analysis should be carried out as soon as possible after sampling.
4. Petiole sap analysis, like dry matter analysis, is an accurate indication of crop N status, but it is just one of the pieces of information that a grower uses to manage a fertilization program.

Table 1. Conversion chart for relating potato petiole sap NO₃-N values to petiole dry matter NO₃-N values, or vice versa. This chart allows the critical values for petiole NO₃-N previously established on a dry matter basis to be applied to the now petiole sap analysis quicktest.

Fertilizer Facts

- Sap analysis is a new approach to petiole testing for N management in potatoes.
- Portable NO₃ meters can be used on-site to analyze petiole sap for NO₃ content, providing immediate information about crop N status to the grower or consultant.
- Established critical values for potato petiole dry matter NO₃ management can be applied to sap analysis by simple conversion.
