

Ammonia loss from surface-applied urea to cold soils: A second look

by Richard Engel and Clain Jones, Land Resources and Environmental Sciences, MSU-Bozeman

INTRODUCTION

Historically urea fertilizer has been surface applied in Montana dryland winter wheat production systems. Often the fertilizer is applied during cold weather months beginning in the late-fall and extending to the early spring. Fertilizing fields separately from seeding is done primarily to expedite seeding operations.

Although urea is an excellent source of N fertilizer, it can be lost to the atmosphere as a result of ammonia (NH_3) volatilization. The process occurs after urea granules applied to the soil surface dissolve and are converted to ammonium (NH_4^+) in a process called "hydrolysis". At the same time, the pH in the soil microenvironment around the granules rises. The rise in pH makes the NH_4^+ unstable and a portion can be lost to the atmosphere as NH_3 gas (Figure 1).

FIGURE 1. Nitrogen in urea applied to the soil surface (left) is susceptible to volatilization after the granules dissolve and the pH of soil around the granule rises.

METHODS

For wheat growers, NH_3 volatilization represents economic loss of fertilizer N, which can potentially affect yield and grain protein. In 2008, we began a study to quantify NH_3 loss from surface-applications of urea and to determine whether applications during cold weather months were susceptible to volatility. This fact sheet provides a summary of the results from 23 trials conducted over 7 years on private farms in

Hill, Fergus and Gallatin Counties. Ammonia losses were quantified using a micrometeorological mass-balance approach (<http://landresources.montana.edu/ureavolatilization/>) with circular plots (0.3 acre), a center mast, and samplers that provided for continuous measurement of NH_3 loss. Ammonia samplers were exchanged approximately once per week over trials lasting up to 12 weeks. This fact sheet is an update of an earlier fact sheet (Number 59).

AMMONIA LOSSES FROM UREA APPLIED TO SOIL SURFACE

Cumulative NH_3 loss, expressed as a percentage of the applied N rate (90 lb N/acre), averaged 16.1% for 23 trials conducted between 2008 and 2014 (Figure 2A). Surface moisture conditions at the time of fertilization and precipitation amounts and distribution following fertilization had a large impact on NH_3 loss.

WORSE CASE SCENARIOS FOR NH_3 LOSS

A commonality of the five trials where NH_3 loss was greater than 20% of applied N was that fertilizer applications were made to soil high in water content, or covered with a modest depth of snow. Precipitation events that followed were light (≤ 0.2 ") and scattered at least through the first 30 days after fertilization. Under this scenario, urea granules dissolve and hydrolysis occurs quite quickly resulting in very high NH_3 loss during the first week following fertilization. One example is provided by a trial west of Havre, MT. Urea was applied to a very moist soil surface with a light dusting of snow (Figure 3A). Within 30 minutes following fertilization, the urea granules started to dissolve (Figure 3B). NH_3 loss was equivalent to 22.4% of applied N over the first week following fertilization as the soil dried (Figure 3C).

A second example is provided by a trial near Denton, MT. Urea was applied onto a modest snow

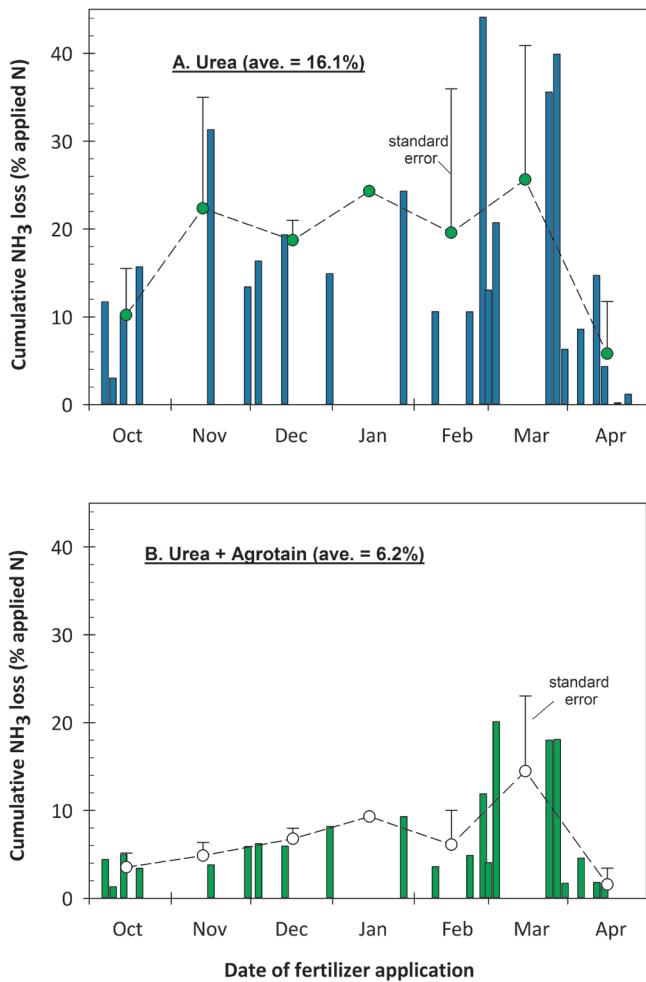

FIGURE 2. Cumulative NH₃ lost from urea (A) and urea+Agrotain® (B) broadcast on the soil surface at different sampling dates. pack (0.35" water equivalent; Figure 4A). Cumulative NH₃ losses were 20.7% of the application rate (90 lb N/acre) over an 8-week period. Losses were particularly large during the second week (6-13 days post fertilization) when the snowpack disappeared and the soil surface dried (Figure 4B and C).

MITIGATION OF NH₃ LOSS

If growers cannot incorporate broadcast urea by tillage or irrigation, they should ideally wait until soil surface is sufficiently dry such that urea granules will not dissolve at the surface until the first precipitation event (Figure 5). If precipitation events (either rain or snow) that follow are light and scattered (e.g., <0.2" per event) then NH₃ losses will typically be in the range of 10 to 20% of applied N. If a large precipitation event (>0.7") follows the application of urea, in particular if they occur within a few days after urea is applied to a dry soil surface, then volatilization loss will likely be <10% of the application rate. In Montana, large

precipitation events typically occur in the spring. Our 7 year study found that NH₃ loss from urea was lower for April applications, than application made Nov to March (Figure 2A). This response was largely due to the occurrence of large precipitation events following fertilization. Conversely, urea applications in Nov, Dec, Jan, Feb, and March all resulted in NH₃ losses that exceeded 10%. Urea applied to soils in the late-fall to winter will typically stay near the surface because the soils are frozen and precipitation which does occur (as snow or rain) does not easily infiltrate into the soil.

Another way to mitigate NH₃ loss from surface

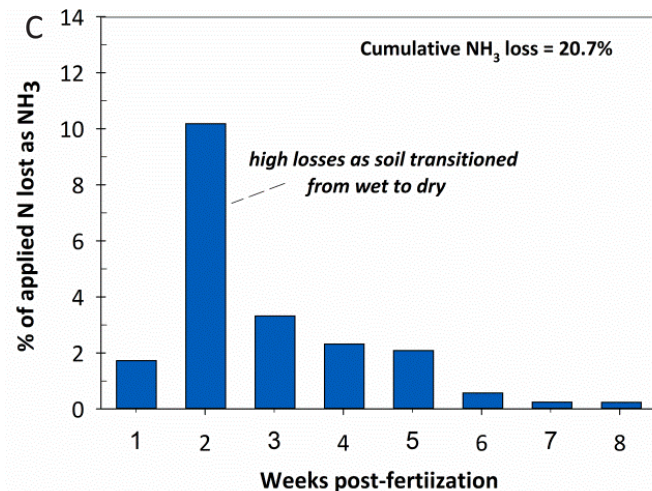

FIGURE 4. Urea applied onto snow March 2, 2011 (A), and snowpack disappearing 6 days later (B). NH₃ loss summary over 8 week trial (C). Note the greatest NH₃ loss occurred during the 2nd week (6-13 days post-application) when the snow pack disappeared and the soil cycled from wet to dry.

applied urea is to treat urea with the products such as Agrotain® that contain the urease inhibitor, N-(n-butyl) thiophosphoric triamide (NBPT). Urease inhibitors slow

FIGURE 5. Urea fertilizer applications to dry soil surfaces will help to mitigate NH₃ losses.

the rate of urea hydrolysis. The N in the urea is converted to ammonium (NH₄⁺), but at slower rate. As a consequence, the soil microenvironment around the urea granule does not experience a large rise in pH, and NH₄⁺ produced is not as readily converted to NH₃ gas. Our 7 year, 23 trial study also examined the impact of treating urea with Agrotain®. Adding Agrotain® typically reduced cumulative NH₃ loss by 60-65% relative to untreated urea (Figure 2B).

FERTILIZER FACTS

- Cold weather conditions do not provide protection against large NH₃ losses from surface-applied urea. NH₃ losses from urea were greater from applications in November to March compared to April.
- Avoid applying urea to soil surfaces that are wet or high in moisture content and frozen. Urea applications onto fields with a modest snowpack can also result in large NH₃ loss (greater than 20% of applied N).
- Volatilization losses from urea can be mitigated by applying urea to dry soil surfaces, and by using urease inhibitor products such as Agrotain®.

ACKNOWLEDGEMENTS

We thank the Montana Fertilizer Advisory Committee, Western Sustainable Agriculture Research and Education, Koch International and NRCS for funding this study.
